## Abstract

One of the current public health concerns is the evaluation of population exposure to toxicants present in food and environment. To do this, high-throughput methods are required to perform a large number of analyses. The aim of this work is to characterize human exposure to xenobiotics. The classification of urines from farmers occupationally exposed to five pesticides was investigated using two analytical techniques, *i.e.* the

3 classical approach based on liquid chromatography coupled to high resolution mass  
4 spectrometry (LC/HRMS) and direct introduction-high resolution mass spectrometry (DI-  
5 HRMS) to produce metabolomics data. Discrimination of different exposure groups was  
6 obtained from LC/MS data as well as from DI-HRMS data thanks to the Independent  
7 Component - Discriminant Analysis (IC-DA). The DIMS approach requiring only a  
8 fraction of the LC/MS analysis time, appears to be very promising for high throughput  
9 epidemiological studies.

## 31 **1. Introduction**

32  
33 The presence of toxicants (*e.g.*, pesticides, drugs, pollutants or contaminants) in food and  
34 environment can impact human health. Due to the great diversity of xenobiotics and the  
35 complexity to develop targeted methods specific to a molecule or a compound family,  
36 global approaches without a priori such as metabolomics seem to be appropriate in such  
37 purpose. Metabolomics <sup>1</sup> is the study of small molecular mass metabolites found in  
38 biological samples, which are involved in growth, metabolic homeostasis or etiology of  
39 disease. It aims at the detection, quantification and subsequent identification of different  
40 metabolic changes arising between two (or more) well-defined but contrasted situations  
41 (*e.g.*, healthy *versus* different unhealthy status). Analytical techniques combined with  
42 statistical and/or chemometric processing tools are essential to compare generated  
43

1  
2  
3 metabolomic fingerprints reflecting phenotypic differences and to reveal the metabolic  
4  
5 biomarkers of a given physiological condition or a pathological state <sup>2</sup>.

6  
7  
8 Among the available analytical technologies, mass spectrometry (MS) providing high  
9  
10 sensitivity, specificity and selectivity, and especially, Fourier transform mass  
11  
12 spectrometry (FTMS) with its very high mass resolving power, high mass measurement  
13  
14 accuracy and wide dynamic range should produce high quality of metabolomic profiles in  
15  
16 term of isobaric species distinction and number of detectable peaks <sup>3,4</sup>. MS-based  
17  
18 metabolomic analysis commonly uses hyphenated methods, typically liquid or gas  
19  
20 chromatography coupled to mass spectrometry (LC/MS or GC/MS). The hyphenated  
21  
22 approaches have the main advantages of being able to separate isobaric and some  
23  
24 isomeric compounds and also to minimize the so-called matrix effects. They should  
25  
26 enhance the metabolome coverage <sup>5,6</sup>. However, they cannot be really considered as high  
27  
28 throughput approaches because of the analysis time. Although the use of ultra high  
29  
30 performance liquid chromatography (UHPLC) can reduce the data acquisition time, its  
31  
32 coupling to the FTMS is done at the expense of the mass resolving power. Furthermore,  
33  
34 the pre-processing of the anisotropic data generated from several scans acquired along the  
35  
36 chromatographic separation requires dedicated pretreatment steps such as peak alignment  
37  
38 and correction for analytical drifts (*e.g.*, retention time and peak intensity). Alternatively,  
39  
40 the direct introduction mass spectrometry (DIMS) approach enabling simultaneous  
41  
42 detection of all ionized compounds provides a seemingly isotropic spectral fingerprint in  
43  
44 a few minutes. Such direct approach can therefore be proposed to increase the throughput  
45  
46 of analyses <sup>7-9</sup>. A comparison between DIMS and LC/MS approaches has been reported  
47  
48 for the analysis of serum samples from kidney cancer patients <sup>10</sup>. A comparable group  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 classification was obtained from both approaches despite the smaller number of  
4  
5 metabolites detected from DIMS data (*i.e.* 23 metabolites compared to a total number of  
6  
7 48 ions from LC/MS data). In addition, only a small fraction of the LC/MS analysis time  
8  
9 (5%) is required to perform the DIMS experiment. Unfortunately, the DIMS approach  
10  
11 using electrospray ionization (ESI) has some limitations, especially the occurrence of  
12  
13 matrix effects. Such phenomena are characterized by ion suppression and/or signal  
14  
15 enhancement, leading to unpredictable signal changes that may affect the quantitative  
16  
17 response of the sample constituents and consequently modify the mass spectrum profiles  
18  
19 <sup>11</sup>. These effects should be overcome or at least minimized through the optimization of  
20  
21 analytical conditions. Sample dilution can be proposed to obtain metabolomics  
22  
23 fingerprints containing the most informative data with minimized matrix effects without  
24  
25 loss of peak intensity <sup>12</sup>. The use of high resolution mass spectrometry (HRMS) such as  
26  
27 FTMS can compensate the absence of chromatographic separation by distinguishing  
28  
29 compounds based on accurate  $m/z$  values and isobar ion resolution. Nevertheless, isomer  
30  
31 distinction requires additional experiments such as the chromatographic separation and/or  
32  
33 MS/MS experiments or other alternative technologies, such as the ion mobility  
34  
35 spectrometry.  
36  
37

39  
40  
41

42 In our previous work, an in-house computational procedure was developed to process DI-  
43  
44 HRMS data using a new discriminant analysis tool based on Independent Component -  
45  
46 Discriminant Analysis (IC-DA). Successfully discrimination of farmers occupationally  
47  
48 exposed to two types of pesticides was obtained, this constitutes the proof of concept of  
49  
50 our approach for high-throughput metabolomics <sup>13</sup>.

2  
3 Most of metabolomic studies concern only few sample groups, typically healthy subjects  
4 *versus* one (or two) group(s) of unhealthy subjects <sup>9,14,15</sup>. Few investigations involving  
5 several classes have been reported, *e.g.*, in the context of dose <sup>16</sup> and time effects <sup>17,18</sup>, but  
6 rarely in the context of human exposure during their lifestyle <sup>19</sup>. The main objective of  
7 this study is to demonstrate the applicability of our high throughput approach to classify  
8 several exposure groups. In addition to DI-HRMS, the hyphenated LC/MS technique was  
9 also employed to phenotype urine samples coming from farmers occupationally exposed  
10 to five different pesticides. Discrimination of the different exposure groups was obtained  
11 from both methods, highlighting the potential of the direct approach to provide  
12 satisfactory results comparable to those obtained by the LC/MS approach but with a  
13 significant gain in the analysis time.

## 31 **2. Experimental**

### 32 **2.1. Materials**

33  
34 Ultra pure water was produced from a Milli-Q system (Merck Millipore, Guyancourt,  
35 France). The highest commercial grade of acetonitrile and formic acid was obtained from  
36 Sigma Aldrich Chemicals (L'Isle d'Abeau-Chesnes, France). Urine samples were  
37 provided by UMR1086 Cancers and Preventions. They were collected from 41 farmers  
38 before and after one day of occupational exposure to pesticides in the cultivated fields.  
39 The exposure conditions have been described by Lebailly *et al.* in a previous work <sup>20,21</sup>.  
40 There are five groups with exposure to: i) isoproturon (with n = 6 individuals), ii) captan  
41 (n = 16), iii) cyprodinyl (n = 7), iv) chlorothalonil (n = 8) and v) epoxiconazole (n = 4).  
42 Note that self-control samples (n=41) are available and correspond to urine of the same  
43

2  
3 subjects collected one-day before pesticide exposure. Note that all procedures performed  
4  
5 in this work were in accordance with the ethical standards of the national research  
6  
7 committee and with the 1964 Helsinki declaration and its later amendments. The  
8  
9 collected urines were stored at -20°C until MS analysis. Urine sample normalization was  
10  
11 done based on the creatinine concentration. Finally, urine samples were diluted at the  
12  
13 chosen dilution factor of 500 after testing various dilution factors. Additionally, a quality  
14  
15 control sample (QC, a pool of all urine samples) was injected after every set of 10 sample  
16  
17 analyses to check for eventual analytical drifts and for the quality of the generated  
18  
19 spectral data.  
20  
21  
22  
23

## 24 **2.2. Mass spectrometry detection**

25  
26 A hybrid LTQ-Orbitrap Fourier transform mass spectrometer (LTQ Orbitrap XL, Thermo  
27  
28 Fisher Scientific, Bremen, Germany) operating in positive ion mode was used to perform  
29  
30 both DIMS and LC/MS analyses. In the DIMS approach, the following ESI conditions  
31  
32 were used: electrospray voltage was set at -3 kV, capillary voltage at 13 V and tube lens  
33  
34 offset at 60 V. Sheath gas flow and auxiliary gas were fixed at 70 and 5 arbitrary units  
35  
36 (a.u.), respectively. The capillary temperature was maintained at 275 °C.  
37  
38

39  
40 Mass spectra were acquired in the  $m/z$  50-1,000 range with a cycle time of 4 minutes per  
41  
42 analysis. A theoretical mass resolving power of 100,000 FWHM (Full width at half  
43  
44 maximum) at  $m/z$  400 was used. Internal mass calibration was performed using mass lock  
45  
46 option on the  $[M + H]^+$  contaminant ions of N-butylbenzene sulfonamide at  $m/z$   
47  
48 214,089625 for both DIMS and LC/MS experiments. Flow injection analysis (FIA) mode  
49  
50 was used to perform DIMS analyses. 10  $\mu$ L of each 500-fold diluted sample were  
51  
52 injected into a 100  $\mu$ L sample loop using a Surveyor LC chromatographic system  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 (Thermo Fisher) at a flow rate of 30  $\mu\text{L}/\text{min}$  of an acetonitrile/water mixture (1:1, v/v)  
4  
5 plus 0.1 % formic acid as eluent. Tandem mass spectrometry (MS/MS) experiments were  
6  
7 performed on the monoisotopic peaks of some metabolite species. The collision-induced  
8  
9 dissociation (CID) conditions, the chromatographic separation and mass spectrometry  
10  
11 conditions used for LC/MS analyses are described in the Supporting Information.  
12  
13

## 14 **2.3. Data analysis**

### 15 **2.3.1 Data pre-processing**

16  
17 An in-house DIMS data processing procedure using Matlab routines (Matlab R2008a,  
18  
19 The MathWorks, Natick MA, USA) was developed in our previous work <sup>13</sup> and was used  
20  
21 in this study to create the DIMS data matrix. Alternatively, the LC/MS data were pre-  
22  
23 processed using XCMS tool based on a program written in R (*R version 3.4.0, The R*  
24  
25 *Foundation for Statistical Computing, Vienna 2017, <https://www.r-project.org>*) as  
26  
27 described in the Supporting Information. The final number of extracted variables for the  
28  
29 82 urine samples was 747 and 2106 from DIMS and LC/MS data, respectively.  
30  
31  
32  
33  
34

### 35 **2.3.2. Chemometric methods**

36  
37 Multivariate analyses were further performed identically on both DIMS and LC/MS  
38  
39 datasets, including all groups in a single model using two Matlab-based chemometric  
40  
41 tools, as already described <sup>13</sup>. Briefly, the first preprocessing tool is the orthogonalization  
42  
43 part of the OPLS algorithm <sup>22</sup>. The second tool is a supervised version of the Independent  
44  
45 Component Analysis (ICA), named IC-DA, as previously described <sup>13</sup>. ICA aims to  
46  
47 extract independent vectors, called Independent Components (ICs), corresponding to  
48  
49 'source signals' with true physico-chemical meaning <sup>23–25</sup>. IC-DA includes group  
50  
51 membership in its calculation to extract signals that discriminate predefined groups.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Therefore, a second calculation was performed using only the spectral signals that  
4 contributed to group discrimination to evaluate if the given group is still separated.  
5  
6 Nevertheless, because of the unbalanced classes in our case, group discrimination can be  
7 oriented by those containing more individuals. To avoid eventual overfitting, a validation  
8 step was then performed using a permutation procedure described in the previous work <sup>13</sup>.  
9  
10  
11  
12  
13

### 14 **2.3.3. Selection and annotation of metabolic biomarkers**

15  
16 A quantile-quantile (Q–Q) plot was used to visualize variables that contribute most to  
17 group discrimination <sup>26</sup>. The most discriminant variables are characterized by high or low  
18 standard deviation values which depart from that linearity while non-interesting variables  
19 that follow a normal distribution are aligned. For each IC, only ions with an absolute  
20 intensity greater than 3 times the standard deviation of all the ions were selected.  
21  
22 Alternatively, an additional procedure was performed to validate the selected  
23 discriminant variables, as well as to highlight their contribution to group discrimination.  
24  
25 In this way, a random selection of 50 % of the individuals from each group, followed by  
26 IC-DA calculations was performed and repeated 3,000 times for every IC. Then, a  
27 quantile calculation with 95 % confidence limit was done on the generated matrix  
28 (variable number  $\times$  5 ICs  $\times$  3,000 repetitions). The discriminant variables characterized  
29 by a quantile sign (*i.e.*, positive or negative) were selected based on their high standard  
30 deviation values. The quantile sign of some selected variables changed after permutation.  
31  
32 Those variables were then removed from the discriminant variable list.  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48

49 Two computational tools such as the box-whisker plot and the Student's t-test were  
50 applied to highlight the contribution of a given variable to the discrimination of one (or  
51 several) exposure group(s). Box-whisker plots should show the abundance variations of a  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 given discriminant variable among all groups, including controls. However, these  
4  
5 variations between groups were not obvious. Therefore, Student's paired t-tests were also  
6  
7 done to reveal variable intensity variations before (self-control) and after exposure for  
8  
9 every individual. The paired data structure was used here only to validate discriminant  
10  
11 variables but it was not applied to all data because rarely each subject could be its own  
12  
13 control (*e.g.*, self-control) in general population monitoring.  
14

15  
16 Afterwards, correlation coefficients were calculated between every selected discriminant  
17  
18 variable and all other (discriminant or not) variables present in the mass spectra in order  
19  
20 to find possible ion associations, *i.e.*, isotopic peaks, in-source fragments and/or adduct  
21  
22 species generated from the same molecule. This calculation improves the compound  
23  
24 annotation and can also reveal eventual biological relations between metabolites (see  
25  
26 results and discussion). Finally, the most discriminant and correlated variables were  
27  
28 putatively annotated using freely available databases (DBs) such as the Human  
29  
30 Metabolome Database (HMDB) <sup>27</sup>, the Kyoto Encyclopedia of Genes and Genomes  
31  
32 database (KEGG) <sup>28</sup> and the METLIN <sup>29</sup> database. The experimental accurate *m/z* values  
33  
34 with four digits after the decimal point were used to query DBs with a mass error below  
35  
36 5 ppm, except for ions with *m/z* values lower than 130 u, where 10 ppm mass error was  
37  
38 used to find candidate compounds.  
39  
40  
41  
42  
43  
44  
45  
46

### 47 **3. Results and discussion**

#### 48 **3.1. Exposure group discrimination**

49  
50 Efficient discrimination of control and pesticide-exposed groups was obtained from both  
51  
52 DIMS and LC/MS data using IC-DA (**Figs. S-1** and **S-2** in the supplementary materials).  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 A given group is typically discriminated from the others by a specific IC. However, these  
4 initial discriminations being obtained taken into account information on the group  
5 membership (*i.e.* dummy variables) are overoptimistic. New calculations only based on  
6 the MS signals contributing to each specific group discrimination, still provide distinction  
7 of all groups as shown in **Fig. 1** and **Fig. S-3** (supplementary materials) for DIMS and  
8 LC/MS, respectively. For the DIMS data, a slight overlap between control subjects and  
9 other groups is observed (**Fig. 1a**). Nevertheless, efficient separation is obtained for  
10 captan, chlorothalonil, cyprodinil and isoproturon exposure groups (**Figs. 1b-e**,  
11 respectively). Additionally, discrimination of the epoxiconazol-exposed group is visible  
12 in another projection dimension, *i.e.* IC2, IC3 and IC5 (**Fig. 1b-e**). A comparable group  
13 discrimination was obtained from LC/MS data (**Fig. S-3**) but the separation of control  
14 subjects from others is less pronounced compared to that for DIMS data (**Fig. S-3a**).  
15 Moreover, no clear distinction of the epoxiconazol-exposed group was obtained from the  
16 LC/MS data.

17  
18

28  
29  
30  
31  
32  
33  
34  
35 The 3D-plots (IC2 vs IC3 vs IC4) from calculations without the group membership  
36 information showed good discrimination of the four exposure groups, *i.e.* those exposed  
37 to captan, chlorothalonil, cyprodinyl, and epoxiconazol for both DIMS and LC/MS data  
38 (**Fig. 2**). Note that the samples from control group are located in the center of the plot and  
39 overlapped with the isoproturon-exposed group into the reported 3D plots. These two  
40 groups were separated in another dimension (**Fig. S-4** in the supplementary materials).

41  
42  
43  
44  
45  
46  
47  
48  
49 Hence, data generated from both the DIMS and the LC/MS approaches give comparable  
50 and successful discrimination of all exposure groups. More interesting, less intra-group  
51 dispersion is observed for DIMS data, enabling better group separation. Such observation  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 suggests that less technical drifts may occur in the high throughput DIMS approach  
4 compared to LC/MS. Importantly, a component characteristic of the control group despite  
5 heterogeneity among individuals could be provided by IC-DA for both data sets. Such  
6 characterization may be useful for large-scale epidemiological studies in which  
7 assignment of control subjects is required for biological interpretation or clinical  
8 assessment.  
9

### 10 **3.2. Detection and characterization of discriminant metabolites**

11  
12 The most relevant variables involved in the group discrimination of the five exposure  
13 types were extracted to be further identified. However, this step is not so easy when  
14 considering several exposure groups. It is less straightforward to highlight the  
15 contribution of a given variable to one (or more) specific exposure group(s) in our case,  
16 compared to classical studies which tend to find the difference between control and an  
17 unhealthy group<sup>9,14,15</sup>. Therefore, different computational tools were used to improve the  
18 selection of the most discriminant ions for every specific exposure group (see  
19 experimental section).  
20

21  
22 First, from the Q–Q plot only discriminant variables characterized by high standard  
23 deviations were extracted. 25 variables and 134 variables were selected from the DIMS  
24 and LC/MS data, respectively, with only four common variables among them. After  
25 concatenating very close m/z variables, the number of highly informative discriminant  
26 variables decreased to 17 and 115 for DIMS and LC/MS, respectively, and to 16 and 56  
27 after application of a permutation procedure (see experimental section).  
28

29  
30 In a second step, box-whisker plots were used to show the ion abundance changes among  
31 all groups. The example of two discriminant variables at m/z 132.0763 and 138.0546  
32  
33  
34

57  
58  
59  
60

1  
2  
3 selected from DIMS data analysis is illustrated in **Fig. 3**. The response of  $m/z$  132.0763  
4 ions is enhanced for samples coming from farmers exposed to captan (**Fig. 3a**),  
5 suggesting a high contribution of these species to reveal captan exposure. For ions at  $m/z$   
6 138.0546, intensity change between groups is less clear (**Fig. 3b**). Their response is  
7 relatively low for the captan exposure group whereas a slightly higher response is  
8 obtained in the other exposure groups, *i.e.* those exposed to isoproturon, chlorothalonil  
9 and cyprodinyl. In this latter case, it is difficult to affirm the significant variation of peak  
10 intensity between different groups. The use of Student's t-test confirmed that 15 variables  
11 among the 16 previously selected were significant for the DIMS data (see experimental  
12 section), demonstrating the robustness of the DIMS approach (**Table 1**). In contrast, the  
13 use of the t-test decreased the number of significant variables from 56 to 29 for the  
14 LC/MS data (**Table S-1**). This indicates that these 27 removed variables are not related to  
15 biological perturbations but that their intensity was probably affected by technical drifts  
16 occurred over a long period of analysis.

17  
18 Finally, correlation coefficients were calculated for each discriminant variable to help in  
19 metabolite annotation. The putatively annotated discriminant variables (in bold) and the  
20 correlated ions detected in the DIMS and LC/MS experiments are reported in **Table 1**  
21 and **Table S-1**, respectively. Among the annotated discriminant metabolites, several di or  
22 tri-peptides (*e.g.*, leucyl-proline), as well as amino-acids (*e.g.*, tryptophan) and amino  
23 acid metabolism intermediates (*e.g.*, creatine, creatinine) were selected from both DIMS  
24 and/or LC/MS data (**Table 1** and **Table S-1**). These di- and tri-peptides have been  
25 described as breakdown products of protein digestion or protein catabolism. However,  
26 their role in physiological function is not well known. Most of them have been reported

1  
2  
3 as short-lived intermediates formed during proteolysis (HMDB, <http://www.hmdb.ca>).

4  
5 Nicotinuric acid, kynurenic acid and xanthurenic acid ions were determined as  
6  
7 discriminant variables from LC/MS data (see the **Table S-1**). They display a decreased  
8  
9 intensity for subjects exposed to captan. Kynurenic acid has already been described as a  
10  
11 metabolite structurally related to xanthurenic acid <sup>30</sup>. Additionally, high level of  
12  
13 xanthurenic acid has been reported to characterize a metabolic perturbation, for example,  
14  
15 as a putative inducer of malaria development in mosquitoes <sup>30</sup>. In our study, the detection  
16  
17 of this metabolite may reflect metabolic disruption for subjects exposed to captan.  
18  
19

20  
21 Alternately, acylglycine species (furoylglycine, nicotinuric acid, hippuric acid), and  
22  
23 carnitine or acylcarnitine derivatives (dehydroxycarnitine, acetyl-carnitine, keto-  
24  
25 decanoylcarnitine, dodecanedioylcarnitine, decadienylcarnitine) were proposed for the  
26  
27 annotation of some discriminant variables (**Table 1** and **Table S-1**). These metabolites  
28  
29 have been described as indicators of disturbed metabolic pathways <sup>31-34</sup>. The unusual  
30  
31 acylcarnitine excretion levels have been reported to be related to diseases such as obesity,  
32  
33 type 2 diabetes, cardiovascular disease, encephalopathy and carcinoma <sup>32,35</sup>. In our study,  
34  
35 the discriminant ions at m/z 204.1230 could be annotated as acetylcarnitine based on their  
36  
37 accurate m/z value (*i.e.* C<sub>9</sub>H<sub>18</sub>NO<sub>4</sub> formulae with 0.5 ppm). However, by comparing with  
38  
39 the CID mass spectrum of the authentic standard compound, the seemingly differences in  
40  
41 the fragment ion abundances suggest that the m/z 204.1230 ions could correspond to an  
42  
43 isomer of acetylcarnitine <sup>36</sup> (**Fig. S-6** of the Supplementary materials).  
44  
45  
46  
47

48  
49 Another example concerns ions correlated to the discriminant ions at m/z 76.0753. The  
50  
51 **Fig. 4** displays a reconstituted DIMS mass spectrum of a urine sample collected on a  
52  
53 subject exposed to chlorothalonil. The m/z 76.0753 ions were putatively annotated as  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 [M + H]<sup>+</sup> ions of trimethylamine N-oxide (C<sub>3</sub>H<sub>10</sub>NO, 5.3 ppm), an oxidation product of  
4  
5 the trimethylamine. This compound has been described as a marker of oxidative stress.  
6  
7 Its high concentration has been reported in transplant patients, reflecting the effects of  
8  
9 kidney diseases <sup>37</sup>. These m/z 76.0753 ions appear to be related to ions at m/z 98.0573,  
10  
11 136.1077, 151.1438, 152.1471 and 189.1345. The presence of ions at m/z 98.0573,  
12  
13 151.1438 and 152.1471 reinforced the assignment of elemental composition of the m/z  
14  
15 76.0753 ions (C<sub>3</sub>H<sub>10</sub>NO, 5.3 ppm) since they could correspond to different species of  
16  
17 trimethylamine N-oxide such as [M + Na]<sup>+</sup> (C<sub>3</sub>H<sub>9</sub>NONa, 3 ppm), [2M + H]<sup>+</sup> (C<sub>6</sub>H<sub>19</sub>N<sub>2</sub>O<sub>2</sub>,  
18  
19 3 ppm) and <sup>13</sup>C isotope peaks of the [2M + H]<sup>+</sup> (<sup>13</sup>C<sub>1</sub><sup>12</sup>C<sub>5</sub>H<sub>19</sub>N<sub>2</sub>O<sub>2</sub>, 3 ppm) ions,  
20  
21 respectively. Additionally, the correlated ions at m/z 136.1077 and 189.1345 could be  
22  
23 annotated as [M + NH<sub>4</sub>]<sup>+</sup> ions of urea, N-hydroxy-N-propyl (C<sub>4</sub>H<sub>10</sub>N<sub>2</sub>O<sub>2</sub>, 3 ppm) and  
24  
25 [M + H]<sup>+</sup> (C<sub>7</sub>H<sub>17</sub>N<sub>4</sub>O<sub>2</sub>, 1 ppm) ions of homo-L-arginine or their isomers, respectively. A  
26  
27 biological connection between these three compounds has already been reported by He et  
28  
29 al. <sup>38</sup>.  
30  
31  
32  
33  
34  
35  
36  
37

#### 38 **4. Conclusion**

39  
40 Discrimination of individuals exposed to the five pesticides was successfully obtained  
41  
42 with both DIMS and LC/MS data. This result demonstrates the applicability of DI-HRMS  
43  
44 approach for metabolomic investigations involving several groups of subjects. More  
45  
46 importantly, the very short data acquisition time makes the DIMS a valuable approach for  
47  
48 performing high throughput metabolomic fingerprinting, in particular for large scale  
49  
50 epidemiological investigations which aim to find associations between exposure to  
51  
52 toxicants and their effects on human health.  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Besides, our approach enabled the detection of some metabolites already described in the  
4 literature (*i.e.* urea, creatinine, carnitine, acylcarnitine, acetylcarnitine,  
5 dehydroxycarnitine, keto-decanoylcarnitine, dodecanedioylcarnitine) as indicators of  
6 toxic exposure. Pesticide exposure has been reported to cause significant DNA damage  
7  
8 <sup>20</sup>, possible effects on fetuses in pregnant women <sup>19</sup> and cardiac dysfunction <sup>39</sup>. Such an  
9 exposure could impact metabolism pathways resulting in changes of metabolite  
10 concentrations <sup>19,34,40–42</sup>. Further studies are needed to provide more accurate  
11 toxicological evaluation and precise identification as well as biological interpretation of  
12 biomarkers specifically related to pesticide exposure.

## LC/MS experimental procedure

### 1. Mass spectrometry detection

LC/MS experiments were acquired in the  $m/z$  100-1000 range with a cycle time of 14 min (including column re-equilibration) using a mass resolving power of 100,000 FWHM (Full width at half maximum) at  $m/z$  400. The following ESI conditions were applied: electrospray voltage was set at -3 kV, capillary voltage at 3 V, capillary temperature at 275 °C and the tube lens offset at 80 V, sheath gas flow (nitrogen) and auxiliary gas were fixed at 66 and 30 arbitrary units (a.u.), respectively.

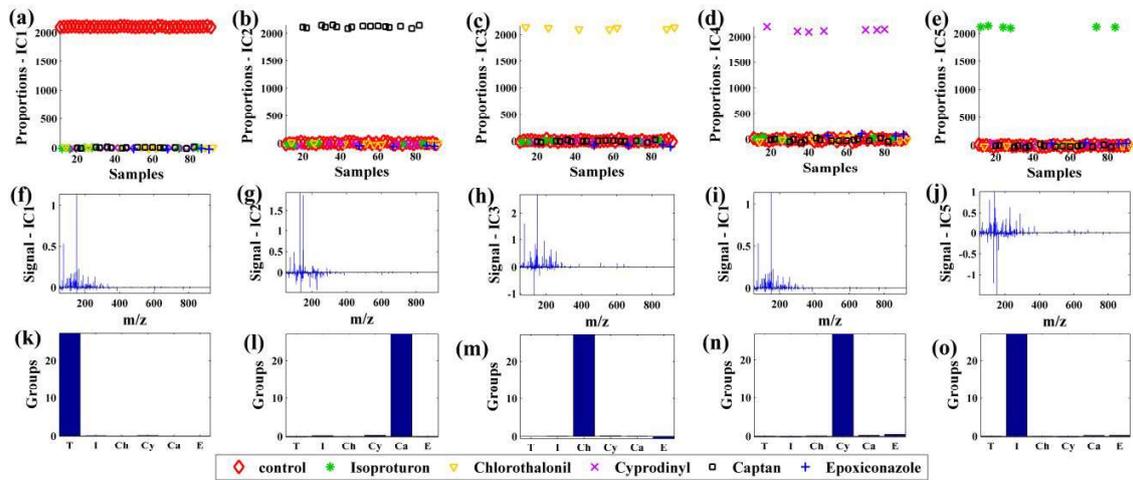

The chromatographic separation was performed using a C<sub>18</sub> NucleodurHTec column (2 × 100 mm, 3 μm, Macherey-Nagel, Eurl, Hoerd, France) and a high performance liquid chromatography system, Surveyor LC (Thermo Fisher Scientific). 10 μL of sample diluted 10 fold in a mixture of acetonitrile/water (1:1, v/v) were injected at a flow rate of 200 μL/min. The mobile phase consisted of water plus 0.1 % formic acid (A) and acetonitrile plus 0.1% formic acid (B). The gradient started with 2% (B) for 1 min, and increased to 100% (B) in 7 min, then was maintained at 100% (B) during 2 min.

### 2. Data pre-processing

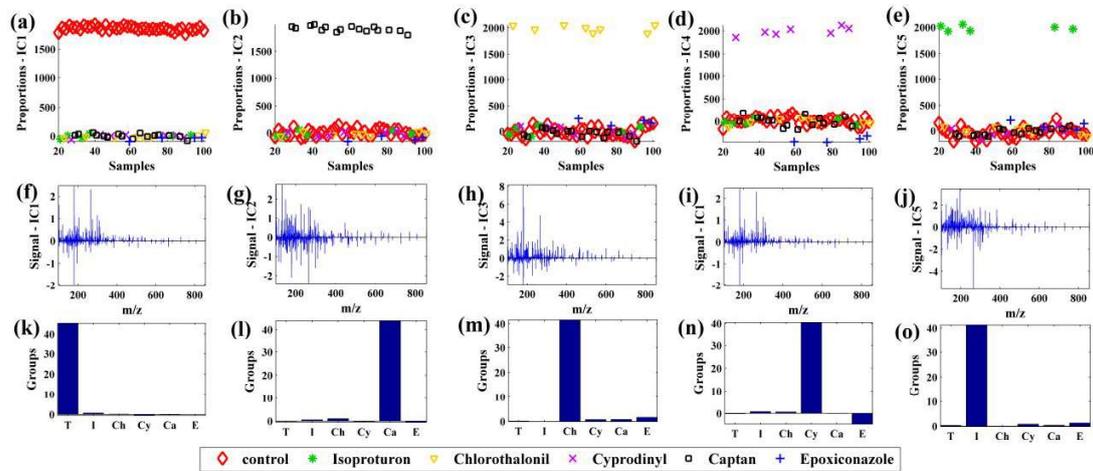

Raw LC/MS data were converted from profile into centroid mzXML format using MS Convert (<http://proteowizard.sourceforge.net/tools.shtml>). XCMS based on a program written in R (*R version 3.4.0, The R Foundation for Statistical Computing, Vienna 2017, <https://www.r-project.org>*) was used to pre-process generated data. Four basic steps corresponding to the peak picking, the peak grouping, the retention time correction, and a second peak grouping were performed. The *centWave* method was used for peak extraction, followed by the correction of retention time drift using a non-linear LOESS alignment method (*Smith C. A. et al., XCMS: Processing Mass Spectrometry Data for Metabolite Profiling Using Nonlinear Peak Alignment, Matching, and Identification.2006, Anal Chem 78:779–787*). Finally, the fill peaks method was applied to find peak intensity in the raw data to correct missing values. The final number of extracted variables from the 82 samples was 2106.

## MS/MS experiments

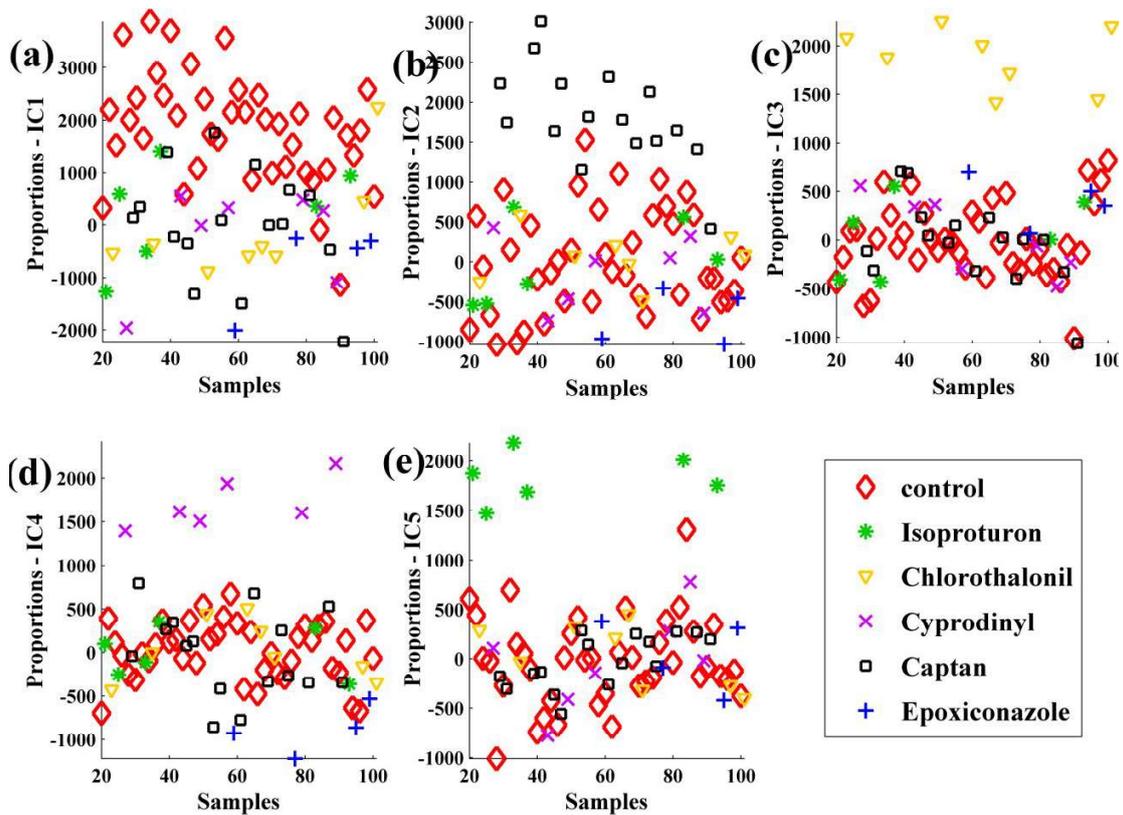

Tandem mass spectrometry (MS/MS) experiments were performed on the monoisotopic peaks of some selected metabolites using CID (collision-induced dissociation) and/or HCD (higher collision dissociation) conditions. The following parameters were used: isolation width of precursor ions of 1 to 2 u, activation time of 30 ms, and normalized collision energy of about 20 % and 38 % (arbitrary units) for CID and HCD, respectively. The precursor ions were selected, fragmented in the linear ion trap (LTQ) device and final high-resolution detection with a mass resolving power of 7500 (FWHM) for  $m/z$  400 was performed.

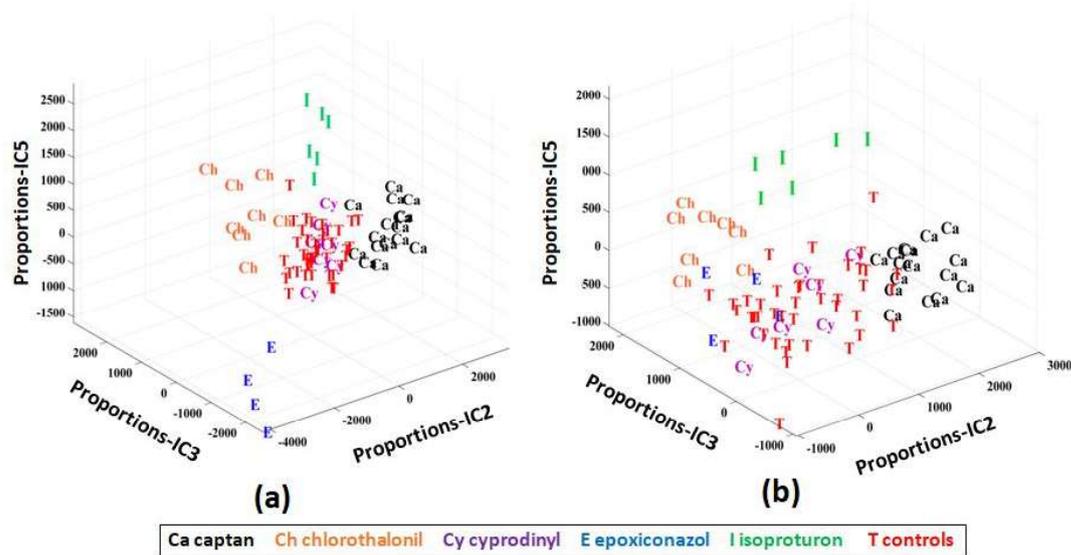

**Fig.S.1** Results obtained from the DIMS data processing with known group memberships. Discrimination of control subjects (a) and the four exposure classes: captan (b), chlorothalonil (c), cyprodinyl (d) and isoproturon (e). The corresponding extracted source signals show the m/z values which most contribute to group discrimination (f, g, h, i and j). The peak intensity represents the ion contribution to the corresponding IC. The part of the source signals belonging to the group membership matrix show which group(s) contribute(s) the most to build the IC when compared to the influence of the others (k, l, m, n and o). Note that no discrimination is observed for epoxiconazole-exposed subjects.

**Fig.S.2** Results obtained from LC/MS data processing with known group memberships. Discrimination of control subjects (**a**) and all exposure classes: captan (**b**), chlorothalonil (**c**), cyprodinyl and epoxiconazol (**d**) and isoprotruron (**e**). The corresponding extracted source signals show the  $m/z$  values which most contribute to group discrimination (**f**, **g**, **h**, **i** and **j** plots). The peak intensity represents the ion contribution to the corresponding IC. The part of the source signals belonging to the group membership matrix show which group(s) contribute(s) the most to build the IC when compared to the influence of the others (**k**, **l**, **m**, **n** and **o**).

**Fig.S.3** Results from LC/MS data processing without the contribution of group information, i.e., based on the only extracted MS source signals. A separation is still observed for captan, chlorothalonil, cyprodinyl and isoprotruron exposure groups (**b-e** respectively). A discrimination of control subjects (**a**) is less apparent and no discrimination of epoxiconazol exposure group is obtained.

**Fig.S.4** 3D-plot from DIMS (a) and LC/MS (b) data processing without the contribution of group information. Discrimination of different exposure groups is observed, especially, separation of individuals exposed to isoproturon according to the proportions of IC-5. Cyprodinyl exposure group was discriminated according to another dimension as observed in **Fig.2**.

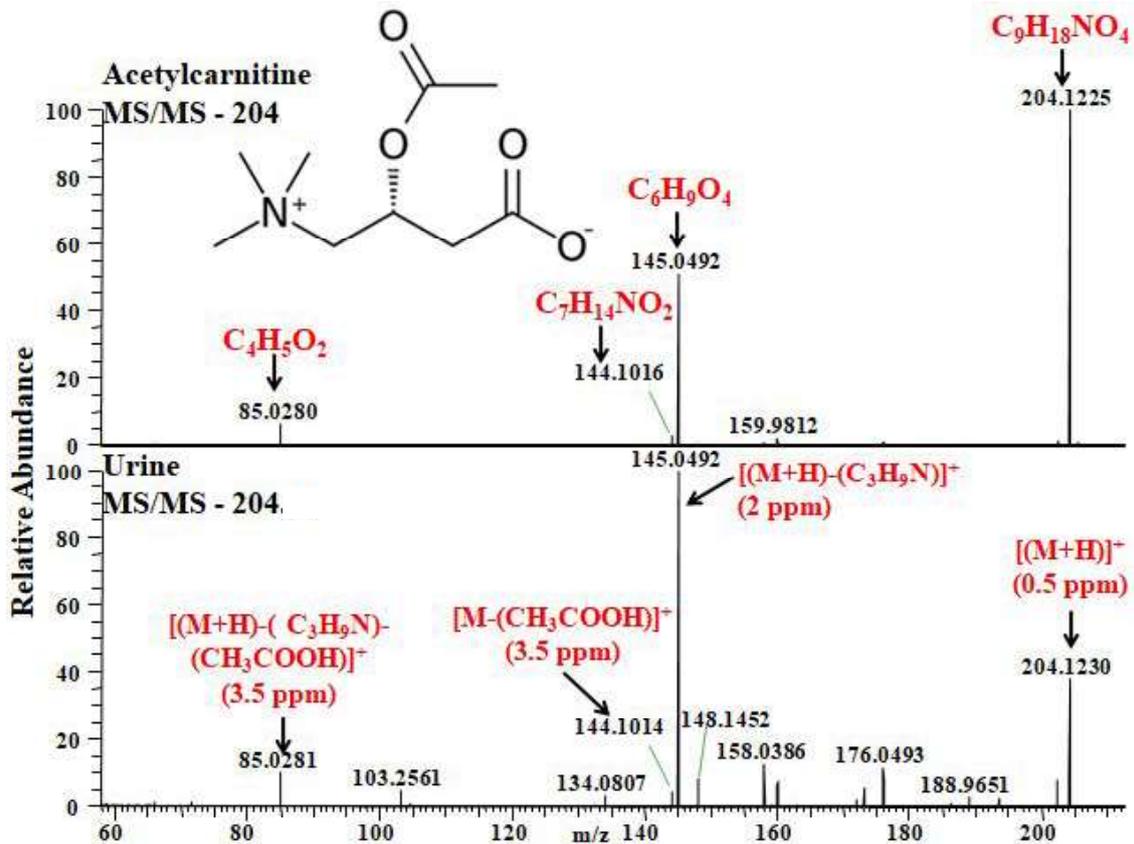

Fig.S.5 MS/MS spectra of the precursor  $[M + H]^+$  ions at m/z 204 (a) from the authentic standard acetylcarnitine and (b) from a urine sample.

‡ Changes between each exposed group and their control one: -, no change; ↗, increase; ↘, decrease; change between all exposed groups and all control: ↗\*, increase; ↘\*, decrease. Horizontal lines separate each set of correlated ions; bold m/z value correspond to the most discriminant variables; the non-bold m/z values are correlated variables with the first one (in bold). <sup>(a)</sup> Note that only one identity was assigned for each variable among the different isomers proposed from DB queries. <sup>(b)</sup> Proposed ion fragment composition or <sup>13</sup>C isotopic peak. Correlated ions without DB hit were eliminated. Some candidates considered unreliable were rejected in the absence of isotopic peaks on the mass spectrum (e.g., absence of the <sup>37</sup>Cl isotopic peak in the mass spectrum since its expected abundance should correspond to 30% and 60% for one and two chlorine atoms, respectively, compared to the monoisotopic peak).
